3D Navigation and Collision Avoidance for a Non-Holonomic Vehicle

Giannis P. Roussos, Dimos V. Dimarogonas, Kostas J. Kyriakopoulos

Abstract—This paper expands the methodology of Navigation Functions for the control of a spherical aircraft-like 3-dimensional nonholonomic vehicle. A Dipolar Navigation Function is used to generate a feasible, non-holonomic trajectory for the vehicle that leads from an arbitrary position to the target, in combination with a discontinuous feedback control law that steers the vehicle. The motion model used incorporates the nonholonomic constraints imposed on an aircraft, preventing any movement along the lateral or perpendicular axis, as well as preventing high yaw rotation rates. The control strategy provides guaranteed collision avoidance and convergence, and is supported by non-trivial simulation results.

I. INTRODUCTION

Potential Field methods in general, and Navigation Functions in particular have been widely used for the control of Nonholonomic robots [4]. Problems addressed include motion planning for a mobile manipulator [18], a mobile robot [19], [15] and multiple manipulators [20]. The aforementioned approaches address 2-dimensional problems, like ground vehicles or aircraft flying on a constant altitude level. There are though applications that are 3-dimensional, like aircraft flying in 3-dimensional space or underwater vehicles, where the above solutions cannot be applied.

Although Navigation Functions as introduced in [16] can be applied to n-dimensional robots and workspaces, holonomic motion model is assumed and required. The adaptation of the methodology to nonholonomic robots is specific for the number of dimensions of each problem, and up to now has only been done for 2-dimensional problems as mentioned above, which assume a unicycle-type motion model. The expansion of the existing 2-dimensional approaches to 3-dimensional problems is not trivial and requires the assumption of an augmented motion model, which will comply with the kinematic constraints present in the real problem.

Nonholonomic systems require special attention since no time-invariant smooth feedback controller can be used to stabilize them [6]. Discontinuous control schemes for the stabilization of a single nonholonomic have been proposed by Astolfi [3], Camadas de Wit et. al. [8] and Bloch et. al. [5]. Previous work on the control of 3D nonholonomic vehicles include approaches by Aicardi et al. based on a velocity vector field [1], [2] and tracking of a 2D path that has been expanded empirically to 3D space [12]. It should be noted though that in these approaches no obstacle avoidance method is used, while the bank angle of the vehicle is not controlled.

This paper aims to present a novel method for the control of a fully 3-dimensional vehicle, namely an aircraft that can fly in 3-dimension space. A kinematic controller implementing a fast discontinuous feedback law in real time is used, that provides provable global convergence, along with a Dipolar Navigation Function [18]. The nonholonomic motion model used takes into account the kinematic constraints on the lateral and perpendicular motion that apply on an aircraft. Furthermore, the control law is engineered to keep the yaw rotation rate minimum, as it is common for a conventional fixed-wing aircraft. This control strategy results in the vehicle following a nonholonomic trajectory that avoids collisions with any obstacles or the workspace boundary and leads to the desired configuration. Being a reactive method, this approach is robust with respect to errors in modeling or measurement.

The rest of the paper is organized as follows: section II describes the system and the problem treated, followed by section III, where the Dipolar Navigation Functions framework used in this paper is presented. In section IV, the feedback control scheme used is introduced and analyzed, while section V includes computer simulation that support the derived results. The conclusions of this paper are summarized in section VI and further research directions are indicated.

II. SYSTEM AND PROBLEM DEFINITION

A. A 6-dof, 4-input 3D non-holonomic vehicle

Consider a 3-dimensional non-holonomic vehicle. The state \( n \) of the vehicle consists of its position \( n_1 \) and orientation \( n_2 \) [11]:

\[
n = \begin{bmatrix} n_1 \\ n_2 \end{bmatrix}, \quad n_1 = \begin{bmatrix} x \\ y \\ z \end{bmatrix}, \quad n_2 = \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \end{bmatrix}
\]

where \( [\phi_1 \ \phi_2 \ \phi_3]^T \) are \( xyz \) Euler angles. Let this Earth-fixed coordinate system follow the NED (North-East-Down) convention with \( x \) pointing North, \( y \) East and \( z \) Down. Consequently \( \phi_1, \ \phi_2, \ \phi_3 \) express bank, elevation and azimuth angles respectively.

The motion of the vehicle is described by:

\[
\dot{n} = \tau = \begin{bmatrix} \tau_1 \\ \tau_2 \end{bmatrix} = \begin{bmatrix} \dot{n}_1 \\ \dot{n}_2 \end{bmatrix}
\]
where \( \tau_1 = \begin{bmatrix} f_1 \\ f_2 \\ f_3 \end{bmatrix} \), \( \tau_2 = \begin{bmatrix} \omega_1 \\ \omega_2 \\ \omega_3 \end{bmatrix} \) are the linear and angular velocities respectively.

As stated above the vehicle under consideration is non-holonomic, resembling an aircraft, i.e. there are non-holonomic constraints, which are expressed in the Body-Fixed coordinate system which is described below:

**Body-Fixed Position and Orientation**

\[
\mathbf{r} = \begin{bmatrix} 1 \\ a \end{bmatrix}, \quad \mathbf{l} = \begin{bmatrix} l_1 \\ l_2 \\ l_3 \end{bmatrix}, \quad \mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix}
\]

where \( l_1 \) points forward, \( l_2 \) to the right and \( l_3 \) downwards with respect to the vehicle.

**Body-Fixed Linear and Angular Velocities**

\[
\mathbf{v} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}, \quad \mathbf{v}_1 = \begin{bmatrix} u \\ v \\ w \end{bmatrix}, \quad \mathbf{v}_2 = \begin{bmatrix} p \\ q \\ r \end{bmatrix}
\]

- \( p, q, r \) are the body-fixed roll, pitch and yaw rotation rates respectively, as shown in Figure 1.

![Fig. 1. Body-Fixed rotations](image)

The transformation between body-fixed and earth-fixed velocities is described in [11]:

\[
\begin{align*}
\mathbf{n}_1 &= \tau_1 = \mathbf{J}_1(n_2) \cdot \mathbf{v}_1 \\
\mathbf{n}_2 &= \tau_2 = \mathbf{J}_2(n_2) \cdot \mathbf{v}_2
\end{align*}
\]

where

\[
\mathbf{J}_1 = \begin{bmatrix}
c\phi_3c\phi_2 & -s\phi_3c\phi_1 + c\phi_3s\phi_2s\phi_1 & c\phi_3s\phi_2 + s\phi_3s\phi_2s\phi_3 \\
-s\phi_3c\phi_2 & c\phi_3c\phi_1 + s\phi_3s\phi_2s\phi_3 & -s\phi_3s\phi_2 + c\phi_3s\phi_2s\phi_3 \\
s\phi_3s\phi_1 + c\phi_3c\phi_1s\phi_2 & -c\phi_3s\phi_1 + s\phi_3s\phi_2c\phi_1 & c\phi_3c\phi_2 + s\phi_3s\phi_2c\phi_1
\end{bmatrix}
\]

\[
\mathbf{J}_2 = \begin{bmatrix}
1 & s\phi_1c\phi_2 & c\phi_1t\phi_2 \\
0 & c\phi_1 & -s\phi_1 \\
0 & s\phi_1 & c\phi_2
\end{bmatrix}
\]

using the notation \( s = \sin(\cdot), c = \cos(\cdot), t = \tan(\cdot) \).

The input vector of the non-holonomic system under consideration is

\[
\mathbf{v}_A = [u \ \omega_1 \ \omega_2 \ \omega_3]^T
\]
i.e. only the longitudinal (body-fixed) linear velocity \( u \) and the three rotation rates (earth-fixed) are actuated, while \( v = w = 0 \). Such a model resembles better the motion of an aircraft as it does not allow any movement along the body-fixed lateral \( l_2 \) or perpendicular \( l_3 \) axis.

Given that according to the selected input vector \( v = w = 0 \), the 2nd and 3rd column of \( \mathbf{J}_1(n_2) \) can be omitted to derive the actual kinematic model of the system treated in this paper by combining (1a) and (1b):

\[
\mathbf{n}'_A = \tau = \mathbf{R}_A(n_2) \cdot \mathbf{v}_A
\]

where \( \mathbf{R}_A = \begin{bmatrix} J_1 & 0 \\ 0 & J_2 \end{bmatrix} \in \mathbb{R}^{6 \times 4}, \quad J_I = \begin{bmatrix} c\phi_3c\phi_2 \\ s\phi_3c\phi_2 \\ -s\phi_2 \end{bmatrix} \)

**B. Problem Statement**

The problem under consideration is to design a control law that will steer the vehicle described by \( \mathbf{2} \) to a desired position and orientation, specifically the origin with zero elevation, azimuth and bank angles, i.e. where \( x = y = z = \phi_1 = \phi_2 = \phi_3 = 0 \) while avoiding collision with any obstacles or the boundary \( \theta W \) of the given workspace \( W \subset \mathbb{R}^3 \). The vehicle as well as the obstacles present in the workspace, and the workspace itself are assumed to be spherical.

**III. Dipolar Navigation Functions**

As discussed above, conventional Navigation Functions are not suitable for the control of a non-holonomic vehicle, as they do not take into account the kinematic constraints that apply on such a vehicle. Use of the original Navigation Function as introduced by Koditschek and Rimon in [16] with a feedback law for the control of a nonholonomic vehicle can lead to undesired behavior, like having the vehicle rotate in place. In order to overcome this difficulty Dipolar Navigation Functions have been developed [20], that offer a significant advantage: the integral lines of the resulting potential field are all tangent to the desired orientation at the origin, eliminating the need for in-place rotation at the origin, as the vehicle is driven there with the desired orientation. This is achieved by using the plane whose normal vector is parallel to the desired orientation, and includes the origin, as an additional artificial obstacle.

The Navigation Function used in this paper is:

\[
V = \frac{\gamma_d}{(\gamma_d^k + H_{nh} \cdot G \cdot \beta_0)^{1/k}}
\]

where:

\[
\gamma_d = ||\mathbf{n}_1 - \mathbf{n}_{1d}||^2
\]

is the distance from the destination position \( \mathbf{n}_{1d} \).

\[
G = \prod_{i=1}^{m_o} g_i
\]
\( g_i = ||n_1 - n_{oi}||^2 - (r + r_i)^2, \quad i = 1, 2, \ldots, n_o \)

with \( r, n_{oi}, r_i \) being the radius of the vehicle, and the position and radius of obstacle \( i \in [1, \ldots, m_o] \), respectively, where \( m_o \) is the number of obstacles. As the workspace is considered spherical with radius \( r_{world} \), the workspace bounding obstacle is \( \beta_0 = r_{world}^2 - ||n_1||^2 - r^2 \).

The factor \( H_{nh} \) is what makes the potential field dipolar. As explained before it is responsible for the repulsive potential created by the artificial obstacle used to align the trajectories at the origin with the desired orientation \( n_{2d} \):

\[
H_{nh} = \epsilon_{nh} + n_{nh} \\
n_{nh} = ||J_{Id} \cdot (n_{1} - n_{id})||^2 \\
J_{Id} = J_1 (n_{2d})
\]

where \( \epsilon_{nh} \) is a small positive constant. Finally, \( k \) is a positive tuning parameter for this class of Navigation Functions.

It was shown in [14] that the potential field created by the Navigation Function defined above has guaranteed navigation properties i.e. it provides global convergence to the destination along with guaranteed collision avoidance. To better demonstrate the properties of a Dipolar Navigation Functions a simple 2-D field is presented in Figure 2, depicting the field in the simple case where no obstacles are present. It can be seen that the surface \( x = 0 \) divides the workspace of radius \( r_{world} = 50 \) in two parts, and forces all the integral lines to approach the target \((0, 0)\) parallel to the \( y \) axis.

![2-D Dipolar navigation Function](image)

**IV. 3D NON-HOLONOMIC NAVIGATION**

**A. Control Law**

The proposed kinematic control law is derived from the one proposed in [18], adapted to the 3-dimensional case:

\[
u = -\text{sgn}(J_T^f \frac{\partial V}{\partial n_1}) \cdot \begin{bmatrix} k_u \cdot ||\frac{\partial V}{\partial n_1}||^2 + k_z \cdot ||n_1||^2 \end{bmatrix} \Rightarrow F_1(n_1)
\]

where \( V = V(n_1) \) is the above Dipolar Navigation Function (3), \( k_u, k_z \) are positive real gains and the functions \( \text{sgn} \) and \( \text{atan2} \) are:

\[
\text{sgn}(x) \begin{cases} 1, & \text{if } x \geq 0 \\ -1, & \text{if } x < 0 \end{cases} \quad \text{atan2}(y, x) \triangleq \text{arg}(x, y), \quad (x, y) \in \mathbb{C}
\]

The angles \( \phi_{id} \) are defined as follows:

\[
\phi_{3d} \triangleq \text{atan2}(\text{sgn}(x)V_y, \text{sgn}(x)V_z) \\
\phi_{2d} \triangleq \text{atan2}\left(-\text{sgn}(x)V_z, \sqrt{V_x^2 + V_y^2}\right) \\
\phi_{id} \triangleq \text{atan2}(\text{sgn}(x)c\phi_2 \cdot c\omega_3, \text{sgn}(x)\omega_2)
\]

The control law for the longitudinal velocity drives the vehicle towards either forward or backwards, depending on the sign of the projection of \( \frac{\partial V}{\partial n_1} \) on the body-fixed longitudinal \( l_1 \) axis, so that the navigation function is decreasing along the direction of movement.

The control law for elevation and azimuth (\( \omega_2 \) and \( \omega_3 \) respectively) is designed so that the vehicle’s longitudinal axis steers to align with the Gradient of the Navigation Function. When \( x < 0 \) the vehicle must approach the target moving forward so it steers towards the direction of \( -\nabla V \), while when \( x > 0 \) the control law steers the vehicle to the direction of \( \nabla V \) in order to approach the target moving backwards.

The bank angle control law (\( \omega_1 \)) is designed so that the vehicle tends to eliminate the yaw rate \( r \) and achieve the required alignment only through pitch rotation \( q \), as is preferable for an aircraft. In other words the body-fixed \( l_3 \) axis is driven to align with \( \nabla V \), the curvature vector of the trajectory defined by the Navigation Function. In fact it can be easily shown that the desired bank angle \( \phi_{1d} \) as defined above eliminates the yaw rate in the body-fixed coordinate system:

Using the inverse transformation \( \mathbf{v}_2 = \begin{bmatrix} p \\ q \\ r \end{bmatrix} = J_2^{-1} \cdot \mathbf{n}_2 \)

where \( J_2^{-1} = \begin{bmatrix} 1 & 0 & -s\phi_2 \\ 0 & c\phi_1 & c\phi_2 s\phi_1 \\ 0 & -s\phi_1 & c\phi_2 c\phi_1 \end{bmatrix} \) the yaw rate (rotation about the \( l_3 \) axis) can be calculated:

\[
r = -s\phi_1 \cdot \omega_2 + c\phi_2 c\phi_1 \cdot \omega_3 \\
= -c\phi_1 (t\phi_1 \cdot \omega_2 - c\phi_2 \cdot \omega_3)
\]

assuming that \( c\phi_1 \neq 0 \). According to the control law \( t\phi_{1d} = \frac{c\phi_1 \omega_2}{c\phi_2} \) and consequently \( r = 0 \). In the case where \( c\phi_{1d} = 0 \) by the definition of \( \phi_{1d} \) we derive that \( \omega_2 = 0 \) so the yaw rate is: \( r = -s\phi_1 \cdot \omega_2 + c\phi_2 c\phi_1 \cdot \omega_3 = 0 \).
B. Tools from Nonsmooth Analysis

In order to facilitate the proof that follows, it is useful to review some tool from the analysis of Nonsmooth Systems.

For a differential equation with discontinuous right-hand side we have the following definition:

Definition 1: [10] In the case of a finite dimensional state-space, the vector function \( x(.) \) is called a Filippov solution of \( \dot{x} = f(x) \), where \( f \) is measurable and essentially locally bounded, if it is absolutely continuous and \( \dot{x} \in K[f](x) \) almost everywhere where \( K[f](x) = \overline{\text{co}}\{\lim_{x_i \to x} f(x_i) | x_i \notin N_0 \} \) and \( N_0 \) is a set of measure zero that contains the set of points where \( f \) is not differentiable.

Lyapunov theorems have been extended to nonsmooth systems in [17], [7]. The following chain rule provides a calculus for the time derivative of the energy function in the nonsmooth case:

\[ \frac{d}{dt} V(x(t)) \in^a.e. \dot{V}(x) := \bigcap_{\xi \in \partial V(x(t))} \xi^T K[f](x(t)) \]

where “a.e.” stands for “almost everywhere”.

In this theorem, \( \dot{V} \) is Clarke’s generalized gradient. The definition of the generalized gradient and of the regularity of a function can be found in [9]. In this paper, the candidate Lyapunov function \( V \) we use is smooth and hence regular, while its generalized gradient is a singleton which is equal to its usual gradient everywhere in the state space:

\[ \partial V(x) = \{ \nabla V(x) \} \forall x \]

We use the following nonsmooth version of LaSalle’s invariance principle in the sequel:

Theorem 2: [17] Let \( \Omega \) be a compact set such that every Filippov solution to the autonomous system \( \dot{x} = f(x), x(0) = x(t_0) \) starting in \( \Omega \) is unique and remains in \( \Omega \) for all \( t \geq t_0 \). Let \( V : \Omega \rightarrow \mathbb{R} \) be a time independent regular function such that \( v \leq 0, \forall v \in \dot{V}(\text{if } \dot{V} \text{ is the empty set then this is trivially satisfied}) \). Define \( S = \{ x \in \Omega | 0 \in \dot{V} \} \). Then every trajectory in \( \Omega \) converges to the largest invariant set, \( M \), in the closure of \( S \).

Uniqueness of solutions is guaranteed by the above definition of Filippov solutions, along with the measurability assumption of \( f \) ([10]).

C. Stability Analysis

Theorem 3: The system (1) under the control law (4) is asymptotically stabilized to \( n = [0 0 0 0 0 0] \).

Proof: We will use \( V \) as a Lyapunov Function Candidate. The generalized time derivative of \( V \) is calculated as:

\[ \dot{V} = \nabla V^T \cdot K[n] = \frac{\partial V}{\partial n_1} \cdot K[n_1] \]

From (4) we derive:

\[ K[u] = K \left[ -\text{sgn} \left( \frac{\partial V}{\partial n_1} \right) \right] \cdot F_1(n_1) \]  

Finally:

\[ \dot{V} = \frac{\partial V}{\partial n_1} \cdot J_1 \cdot K \left[ -\text{sgn} \left( \frac{\partial V}{\partial n_1} \right) \right] \cdot F_1(n_1) \]

\[ = - \frac{\partial V}{\partial n_1} \cdot J_1 \cdot F_1(n_1) \leq 0 \]

By the non-smooth version of LaSalle’s invariance principle (Theorem 2) we deduce that the system converges to the largest invariant subset included in the set \( S \triangleq \{ n \mid 0 \in \dot{V} \} \).

Within \( S \), we have

\[ 0 \in \dot{V} \iff \frac{\partial V}{\partial n_1} \cdot J_1 \cdot F_1 \leq 0 \]

The above conditions

\[ F_1 = 0 \]

and

\[ J_1 \frac{\partial V}{\partial n_1} = 0 \]

define two intersecting sets:

\[ S_1 \triangleq \{ n \mid F_1 = 0 \} \]

\[ S_2 \triangleq \{ n \mid J_1 \frac{\partial V}{\partial n_1} = 0 \} \]

with \( S_1 \cup S_2 = S \). (6a) represents the case where \( \frac{\partial V}{\partial n_1} = 0 \) i.e. the gradient of the potential field is zero, and the current position is the origin i.e. \( x = y = z = 0 \), while the second condition (6b) is satisfied when the gradient vector is normal to the aircraft’s longitudinal axis.

For \( S_1 \) where \( F_1 = 0 \), by the definition of \( F_1 \) we have \( \frac{\partial V}{\partial n_i} = 0 \) and consequently \( \frac{\partial V}{\partial n_i} = 0 \), \( i = 1, 2, 3 \), which yields

\[ \phi_i = 0, \ \ i = 1, 2, 3 \]  

(7)

Let us then define the subset

\[ S_3 \triangleq S_1 \cap \{ n \mid \phi_i = 0, \ i = 1, 2, 3 \} \subset S_1 \]

which is the origin with the desired zero azimuth, elevation and bank angles. By the control law (4) then we deduce:

\[ \omega_i = 0 \iff \phi_i = 0 \text{ for } i = 1, 2, 3 \]

Furthermore \( u = 0 \) inside \( S_1 \supset S_3 \), so \( S_3 \) is the only invariant subset of \( S_1 \).

For the set \( S_3 \setminus S_2 \subset S_2 \), where \( J_1 \frac{\partial V}{\partial n_1} = 0 \) and \( F_1 \neq 0 \), the potential field’s gradient is non-zero and normal to the aircraft’s longitudinal axis. In this case, as it will be
proven by contradiction below, at least one of the elevation and azimuth angular velocities \( (\omega_2, \omega_3) \) is non-zero and steers the vehicle away from this set:

Suppose that the set \( S \backslash S_1 \) is invariant, then \( \omega_i = 0 \) for \( i = 1, 2, 3 \), which by (4b) means that

\[
\phi_{id} = \phi_i
\]

Then by the definition of \( \phi_{2d} \) and \( \phi_{3d} \) we derive:

\[
s\phi_2 = \frac{\text{sgn}(x)V_z}{\sqrt{V_x^2 + V_y^2 + V_z^2}} \quad s\phi_3 = \frac{\text{sgn}(x)V_y}{\sqrt{V_x^2 + V_y^2}}
\]

\[
c\phi_2 = \frac{\sqrt{V_x^2 + V_y^2}}{\sqrt{V_x^2 + V_y^2 + V_z^2}} \quad c\phi_3 = \frac{\text{sgn}(x)V_z}{\sqrt{V_x^2 + V_y^2}}
\]

when \( \sqrt{V_x^2 + V_y^2} \neq 0 \) so that \( s\phi_3, c\phi_3 \) can be calculated as above.

Since the Navigation Function \( V \) is polar with exactly one minimum of zero value at the origin, \( F_1 \neq 0 \) means that

\[
\left| \frac{\partial V}{\partial n_1} \right|^2 \neq 0 \quad \text{and} \quad ||n_1||^2 \neq 0,
\]

i.e. outside \( S_1 \) the navigation function and its gradient ||\( \nabla V \)|| = \( \sqrt{V_x^2 + V_y^2 + V_z^2} \)

are always non-zero and consequently \( s\phi_2, c\phi_2 \) can be calculated in the above way. Substituting in (6b) we get:

\[
\text{sgn}(x) \left[ V_x^2 + V_y^2 + V_z^2 \right] = 0 \quad \text{which is not possible outside \( S_1 \).}
\]

Thus it has been shown that when \( \sqrt{V_x^2 + V_y^2} \neq 0 \)

inside the set \( S \backslash S_1 \) the condition (8) cannot hold and consequently by (4b) at least one of \( \omega_2, \omega_3 \) is non-zero.

In the trivial case where inside \( S \backslash S_1 \) \( \sqrt{V_x^2 + V_y^2} = 0 \Leftrightarrow V_x = V_y = 0 \) (i.e. the gradient is perpendicular) then \( V_z \neq 0 \)

and \( s\phi_2 \neq 0 \), so (6b) yields \( \text{sgn}(x)s\phi_2V_z = 0 \) which cannot hold, proving again that (8) cannot hold in this case either.

We have shown then that in the set \( S \backslash S_1 \) at least one of the angular velocities \( \omega_2, \omega_3 \) is non-zero, so the set is not invariant. This proves that the only invariant set in \( S \), where every trajectory of the system converges under the proposed control law, is \( S_3 \), i.e. the origin with zero elevation, azimuth and bank angle.

V. SIMULATION

The control strategy presented above has been used on a computer simulation. The test case consisted of a workspace with \( r_{\text{world}} = 150 \), containing 3 obstacles of various radii scattered in the workspace. The initial configuration of the vehicle has been set at

\[
n_{\text{init}} = \left[ \begin{array}{cccccc}
-90 & 90 & 30 & 0 & \frac{\pi}{2} & -\frac{3\pi}{2}
\end{array} \right]^T
\]

The goal is to drive the vehicle to the origin with zero azimuth, elevation and bank angles, where

\[
x = y = z = \phi_1 = \phi_2 = \phi_3 = 0
\]

The results are presented in the following Figures, showing the trajectory of the vehicle from 3 different viewing angles.

As Figures 3, 4 and 5 demonstrate, the vehicle follows a feasible, nonholonomic 3-dimensional path avoiding all the obstacles, and converges to the origin with the desired orientation. Furthermore, it can be seen that the bank angle control law rotates the vehicle so that the body-fixed yaw rotation rate is maintained low, as intended. The efficiency of this is further demonstrated in Figure 6, where the yaw
rotation rate is presented, in comparison with the 3 earth-fixed rotation rates.

VI. Conclusions

This paper presents a novel application of the Navigation Functions’ methodology to the control of a 3-dimensional aircraft-like non-holonomic vehicle. The control scheme uses a Navigation Functions along with a discontinuous feedback control law. The result is a 3-dimensional non-holonomic trajectory leading to the target position with the desired orientation. The use of a feedback law makes the control strategy robust with respect to measurement and modeling errors, while the Navigation Function provides guaranteed global convergence and collision avoidance.

Further research includes the use of body-fixed velocities for the control, so that more non-holonomic constraints can be imposed (like zero yaw rotation rate). Furthermore, tuning the Navigation Function in order to impose a certain curvature vector at the origin can offer better control over the bank angle. Finally the expansion of the methodology for multiple vehicles is expected.
